Abstract—Fault-tolerant quantum computation fundamentally relies on encoding a logical qubit into a structured block of physical qubits, typically in the tens to hundreds. As a trade-off for improved fault-tolerance, logical gate operations will incur a linear overhead, in terms of both the amount of time and quantum resources, than before. For example, in monolithic quantum computing, performing a gate operation on two distant logical qubits will first require using a linear number of SWAP operations in order to move the logical qubits next to each other; while in distributed quantum computing, doing so will first require a linear number of ancilla qubits in order to form entanglement connections (or a logical Bell pair).

In this paper, we focus on significantly reducing the overhead involved in logical CNOT operations, a fundamental primitive. We propose NOBOL, a novel approach that requires only one Bell pair to perform a logical CNOT operation on two distant qubits encoded in arbitrary Calderbank–Shor–Steane (CSS) codes. More importantly, NOBOL only requires performing gate operations on the logical X or Z operator subsets of the logical qubits. For many CSS codes, such as the surface code, these subsets are significantly smaller than the size of the code itself. In this paper, we describe various circuit realizations of NOBOL, including a depth optimal circuit with logarithmic depth in terms of the size of the logical operators. Finally, we propose effective methods to contain error propagation without incurring much additional overhead.

Since NOBOL can be effectively applied to a wide range of quantum error-correcting (QEC) codes, and in addition, is agnostic to qubit modalities and effective for various architectures, including those based on either a monolithic QPU or distributed QPUs, we believe that this work makes a significant contribution to advancing large-scale fault-tolerant quantum computing and Quantum Internet.

I. INTRODUCTION

Quantum computing offers the potential for significant speedups in a variety of applications, such as integer factorization, discovery of new materials, and combinatorial optimization by exploiting unique quantum phenomena such as superposition and entanglement [1]–[4]. Despite these promising advantages, current quantum hardware remains highly error-prone and constrained in the number of available physical qubits (thus classified as noisy intermediate-scale quantum or NISQ devices).

To address the fragility of quantum states, quantum error correction (QEC) codes encode quantum information across a block of entangled physical qubits into one logical qubit to improve resilience to noise and errors [5]. QEC enables detection and correction of errors, which forms the foundation for fault-tolerant quantum computing [6]. However, this redundancy-based mechanism further amplifies the demand for physical qubits, thereby exacerbating scalability challenges. In this context, distributed quantum computing (DQC) has emerged as a promising paradigm, where multiple small quantum processing units (QPUs) are interconnected. Through a quantum data network [7], [8] and classical communication links, a larger virtual QPU can be formed. DQC provides a scalable pathway to overcome qubit limitations and facilitates large-scale fault-tolerant quantum computing [9]–[13].

Fault-tolerant quantum computing not only relies on a collection of error management techniques, including error suppression, error correction, and error containment, but also requires a fault-tolerant universal set of gate operations. A fundamental approach to constructing fault-tolerant gate implementations is through transversal operations. In CSS codes [14], [15], single-qubit transversal gates are realized as tensor products of independent operations applied to each physical qubit in a code block, while multi-qubit transversal gates are implemented in a bitwise manner, acting on corresponding pairs of qubits across different code blocks.

The CNOT gate is one of the most fundamental two-qubit operations in quantum computing due to its prominent role in entanglement generation, and its contribution to forming a universal gate set (together with the T and H gates). It plays a central role in QEC, distributed quantum protocols, and the implementation of logical operations, which makes it a key determinant of both computational capability and system performance [16]. Since CNOT is a Clifford gate, for many QEC codes, CNOT has a transversal implementation, and, when the logical qubits are neighboring each other on the same QPU, this operation is trivial. However, if the qubits are non-neighboring, then SWAP gates are required, which increases overhead. Other approaches, such as lattice surgery or lattice braiding incur similar overhead when the logical qubits are non-neighboring.

The overhead becomes worse when considering distributed

systems. If the logical qubits are on separate QPUs, then several entanglement links are required to perform the operation transversely. CNOT can be implemented using parity-based-measurement approaches, such as distributed lattice surgery [17]–[19]. However, this method also requires numerous Bell pairs. It is possible to perform remote operations at the logical level using logical gate or logical qubit teleportation. Nevertheless, even these approaches incur overhead through the formation of logical Bell pairs. More specifically, this dependence on logical entanglement resources introduces substantial overhead in terms of resource consumption, communication rounds, and sensitivity to errors. In many cases, the resource cost of a distributed logical operation scales unfavorably with the code distance, further amplifying the burden of fault tolerance. Moreover, repeated entanglement generation and classical feedback introduce latency that can degrade overall system performance. In short, remote logical gate operations pose a key roadblock towards large-scale quantum computing via e.g. DQC.

In this paper, we propose NOBOL, a novel low-overhead approach for implementing logical CNOT operations that significantly reduces reliance on entangled resources and ancilla qubits. NOBOL aims to reduce the overhead in both the monolithic case, where the qubits are non-neighbor, and in the distributed case, where the qubits reside on separate QPUs. NOBOL enables the realization of a logical CNOT between two encoded qubits using only a single entangled state (e.g., a Bell pair). This Bell pair is first established and distributed at the same two locations as the two logical qubits. *Thereafter, only local operations at both locations, involving one half of the Bell pair and one logical qubit at the same location, are performed.*

The proposed design eliminates the need for excessive SWAP operations when the logical qubits involved in the same CNOT operation reside on the same QPU but are non-neighbor, and greatly benefits distributed multi-QPU architectures. By requiring only a single shared entangled state, independent of the block size, NOBOL relaxes key hardware constraints associated with entanglement generation, distribution, and preservation. This feature makes it well-suited for near- and mid-term large-scale quantum platforms, where interconnects remain a critical bottleneck.

More specifically, consider a logical CNOT operation on two remote logical qubits, A_L (as the control) and B_L (as the target), where A_L and B_L are each encoded using a CSS code with block size N , typically in tens to hundreds. A_L and B_L can be encoded using any arbitrary CSS code as the method is code agnostic; it only works with the logical operators. Let A_{Z_L} and B_{X_L} be the subset of the physical qubits in the block encoding A_L and B_L respectively, that support a logical Z and X operators of A_L and B_L , respectively. For simplicity, assume that the size of each subset is τ , which typically can be much smaller than N (for example, in a surface code, $\tau = \sqrt{N}$). Further, denote the two ancilla qubits that share the single entangled Bell state by q and q' , respectively.

NOBOL implements CNOT (A_L, B_L) by first establishing

and distributing the Bell pair such as that q and q' are at the same location as B_L and A_L , respectively to facilitate the subsequent local operations. Thereafter, it uses (1) only $2\tau - 1$ local CNOT gates on q and the physical qubits in B_{X_L} , along with (2) an additional $2\tau - 1$ local CNOT gates on q' and the physical qubits in A_{Z_L} . The proposed design admits a factorial number of circuit realizations due to the flexibility in qubit ordering, while its depth-optimal implementation achieves a depth of $O(\log(\tau))$. This combination of structural flexibility and shallow circuit depth enables diverse mappings onto hardware architecture to accommodate hardware constraints and aligns well with coherence-time requirements in fault-tolerant quantum computing. Finally, in this paper, we introduce lightweight mechanisms to enhance fault tolerance by incorporating intermittent stabilization and encoding q and q' using small repetition codes.

While this work does show it is possible to perform logical operations with a single physical Bell pair, naturally, this method will reduce the fault tolerance of the operation as redundancy has been eliminated. Thus, we provide error containment procedures for improving the fault tolerance. The issue is a single error can spread to other data qubits causing a logical error. One method to prevent the error propagation is to perform intermittent stabilization, and the other method is to encode each half of the Bell pair in small repetition codes to distribute the operation within the code block. Each error containment procedure has its own trade-off in terms of execution time and ancilla qubit use.

Given that NOBOL can be effectively applied to a wide range of quantum error-correcting (QEC) codes, including arbitrary CSS codes, and in addition, is agnostic to qubit modalities and effective for various architectures, including those based on either a monolithic QPU or distributed QPUs, NOBOL is compatible with a wide range of qubit modalities and QEC codes, we believe that this work makes a significant contribution to advancing large-scale fault-tolerant quantum computing and Quantum Internet.

The remainder of this paper is organized as follows. Section II provides background on distributed quantum computing, logical qubits, and logical operations. Section III presents the NOBOL design, including its various structural implementations and optimal-depth constructions. Error containment techniques for fault-tolerant implementations of NOBOL are detailed in Section IV. Finally, Section V concludes the paper.

II. BACKGROUND AND PRELIMINARIES

A. Distributed Quantum Computing

Distributed quantum computing architectures comprise multiple quantum processing units interconnected via quantum data networks (QDN) [7], [8] classical communication channels. Each QPU can perform local operations on its encoded logical qubits, while remote logical operations are typically enabled through the generation and consumption of entangled states between modules [9]. This modular paradigm alleviates several limitations associated with monolithic quantum computing (MQC), including limited qubit counts, constrained

Fig. 1: Remote CNOT operation between A and B . A and B are physical qubits residing on two locations, e.g. QPUs. $|\Psi^+\rangle$ is a Bell pair state distributed between the two locations.

qubit connectivity, control complexity, and fabrication constraints.

The dominant cost driver in DQC is the realization of remote operations across QPUs. Despite their non-local nature, such operations can be implemented using only local operations and classical communications (LOCC). The canonical example is the remote CNOT gate illustrated in Fig. 1, which leverages a pre-distributed Bell pair between QPUs, given by Equation 1.

$$|\Phi^+\rangle = \frac{|00\rangle + |11\rangle}{\sqrt{2}} \quad (1)$$

In this construction, all quantum gates are executed locally within each QPU, while classical communication is used to transmit measurement outcomes and apply conditional correction operations, effectively realizing a remote CNOT gate [20]. In practice, the efficiency of such remote gate operations is fundamentally constrained by the underlying entanglement distribution techniques. Entanglement between QPUs is typically established via photonic interconnects or similar networking techniques, which are inherently probabilistic and subject to noise and loss. As a result, entanglement generation exhibits limited success probability and introduces non-negligible latency [21], [22]. The expected time required to establish a Bell pair of fidelity $F < 1$ can be expressed by Equation 2.

$$T_{\text{link}} = \frac{1}{p_{\text{link}}} T_0 \quad (2)$$

where p_{link} denotes the success probability of entanglement generation and T_0 is the duration of a single attempt [23]–[25]. As indicated by (2), low success probabilities directly result in increased latency, which influences remote gate operations. Consequently, the performance of remote logical gate operations is tightly coupled to the cost of entanglement generation and distribution. This dependency introduces a fundamental bottleneck in DQC systems, where communication overhead, latency, and accumulated errors from repeated entanglement attempts significantly impact scalability and overall system performance.

B. Quantum Error Correction and Logical Qubits

Fault-tolerant quantum computation relies on encoding quantum information into a block of N physical bits as each logical qubit, which is intrinsically more robust against physical noise through redundancy and active error correction. The reliability of such encoded qubits is typically determined by code distance d , which quantifies the error-correcting capability and directly impacts the scaling of the logical error rate. Under standard assumptions, the logical error rate P_L per round of error correction can be approximated as Equation 3.

$$p_L \approx C \left(\frac{p}{p_{th}} \right)^{(d+1)/2}, \quad (3)$$

where p is the physical error rate, p_{th} is the error threshold of the QEC code¹, and C is a constant that depends on the decoder and circuit-level implementation details [26]. As indicated by (3), increasing the code distance exponentially suppresses logical errors, at the cost of substantial overhead in physical qubits and operations.

Topological codes, particularly the surface code, have emerged as leading candidates for fault-tolerant architectures due to their locality constraints and relatively high error thresholds [26]–[28]. However, logical operations in such codes must be carefully engineered to preserve fault tolerance, typically requiring structured sequences of physical gates, mid-circuit measurements (MCMs), classical feedforward, and continuous stabilization of the encoded state. These requirements introduce non-trivial overheads, especially for remote logical operations, where maintaining fault tolerance becomes increasingly challenging.

C. Distributed Logical Gate Operations

Realizing logical operations across spatially separated QPUs is a central challenge in DQC, as it requires coordinating encoded qubits under strict fault-tolerance constraints. A broad class of approaches relies on extending local fault-tolerant constructions to the distributed architectures, typically through entanglement-assisted designs. A straightforward strategy is to apply transversal operations across QPUs for Clifford gates. In this approach, a remote logical CNOT is decomposed into pairwise remote physical CNOT gates between corresponding qubits of the two code blocks, implemented via remote CNOT primitives as depicted in Fig. 1. This transversal-based design requires N independent entanglement pairs, if logical qubits are encoded in N physical qubits, resulting in a linear scaling of communication and entanglement resources with the code size [16]. While this method preserves fault tolerance due to its transversal structure, the associated entanglement overhead and synchronization cost become prohibitive for large code distances. An alternative class of methods realizes logical operations indirectly through parity measurements, which require an ancilla qubit to mediate joint measurements between data

¹The maximum physical error rate below which QEC can successfully suppress errors by increasing the code distance.

Fig. 2: CNOT circuit with single qubit as control. **(a)** The desired CNOT operation; q is the control and B_L is the target. **(b)** The proposed method; only qubits within B_{X_L} need to be acted upon. The method is comprised entirely of CNOT gates. The target locations and a few controls are fixed, as shown in the figure, but most of the control qubits for each target have several possible locations. The Ct rectangle denotes all possible locations for the control qubit, with an implicit requirement for symmetry in their locations in the circuit.

qubits. For instance, the CNOT gate can be performed as follows.

- Perform a joint $Z \otimes Z$ measurement between the control qubit and ancilla qubit.
- Perform a joint $X \otimes X$ measurement between the ancilla qubit and the target qubit.
- Measure the ancilla qubit and apply conditional corrections to the control and target qubits.

This measurement-based construction has been extended to distributed settings using entanglement-assisted techniques [17], [18], [29]. However, such approaches are typically designed at the physical level and do not directly account for the structure of encoded logical qubits. At the logical level, this method is typically realized through lattice surgery, particularly for topological codes such as the surface code. In this strategy, logical operations are implemented by dynamically merging and splitting code patches to perform joint stabilizer measurements [30]. While lattice surgery preserves locality and fault tolerance, it requires additional logical ancilla qubits and incurs non-trivial space-time overhead. In a distributed setting, it also amplifies the dependence on high-fidelity entanglement and introduces additional communication latency and error sources in distributed architectures [19]. Indeed, for typical 2D surface codes whose code-distance d (and N is approximately d^2), a total of $O(d^2)$ Bell pairs will still be needed. This is because in each round, d Bell pairs are needed, and $O(d)$ rounds are needed for a remote CNOT based on lattice surgery [31], [32].

Progress has been made towards more efficient logical operations. For instance, lattice surgery can reduce memory overhead by a factor of 4 [33]. This work also significantly reduces the overhead of magic state distillation and injection. More recent work has shown that noisy entanglement links can be tolerated in distributed lattice surgery when merging

two patches [34]. This type of improvement would allow for less overhead with entanglement distillation. Another recent work presented a more general form of lattice surgery that can be applied to any quantum low density parity check code, and it reduces the number of stabilization required for the operation [35]. This method could reduce the number of Bell pairs required in the distributed setting. Our work differs from these recent advances by reducing the number of required Bell pairs to only one, which is a significant improvement over the previously mentioned methods. NOBOL may require extra ancilla qubits, but the entire operation can be completed with a single entanglement connection.

III. NOBOL: PROPOSED DESIGN

In this section, we describe the design of NOBOL, a low-overhead, fault-tolerant logical CNOT operation between two remote logical qubits, A_L (control) and B_L (target), encoded using CSS codes, using only one Bell pair distributed at the same locations as A_L and B_L , respectively, to minimize entanglement and ancilla overhead. To this end, we generalize the standard remote CNOT construction based on LOCC for physical qubits shown in Fig. 1 and apply it at the logical level, while still leveraging only a single shared Bell pair, independent of the code size. Table I shows the symbols we use throughout this section and their meanings. Any symbol without a subscript A or B is meant to refer to a general logical qubit, and not necessarily A_L or B_L .

Below, we first develop efficient designs for implementing a local CNOT operation between a logical qubit and a single physical qubit (e.g., one half of the Bell pair), for the two cases where the former is the control and the latter is the target and vice versa. We then show that combining the two designs is sufficient to construct a long-distance (or remote) logical CNOT between two encoded qubits, A_L and B_L .

A. Single Qubit as Control, Logical Qubit as Target

The conventional physical-level remote CNOT gate requires a CNOT operation between one-half of a shared Bell pair and the target qubit. Extending this construction to the logical level necessitates the implementation of a CNOT gate in which a single physical qubit acts as the control and a logical qubit serves as the target. This operation constitutes a fundamental primitive underlying our proposed design of NOBOL.

More specifically, let q denote a single control qubit in an arbitrary quantum state, and let B_L represent a logical qubit encoded using a CSS code. By definition, the logical X_L operator on B_L can be implemented through applying a tensor product of Pauli- X operations over a subset of its physical qubits, denoted by $B_{X_L} \subseteq B_L$. It should be noted that B_{X_L}

TABLE I: Symbols Used

Symbol	Meaning
N_A	Total number of physical qubits in A_L
τ_A	Number of qubits in the logical Z operator for A_L (A_{Z_L})
N_B	Total number of physical qubits in B_L
τ_B	Number of qubits in logical X operator for B_L (B_{X_L})

can be significantly smaller than the full code block B_L . For instance, in a surface code with N physical qubits, the logical X_L operator typically spans only $\sqrt{N}$ qubits. This observation leads to a fundamental intuition, in which the logical CNOT gate can be realized by interacting only with subset of the qubits, B_{X_L} , while leaving the remainder of the code block unaffected, as illustrated in Fig. 2(a). Let $N_B = |B_L|$ and $\tau_B = |B_{X_L}|$ denote the size of the logical qubit B and weight² of logical X_L operator on logical qubit B , respectively. The desired logical CNOT operation can then be expressed as the block-diagonal unitary matrix as Equation 4.

$$U_{\text{L-CNOT}} = \begin{bmatrix} I^{\otimes \tau_B} & 0^{\otimes \tau_B} \\ 0^{\otimes \tau_B} & X^{\otimes \tau_B} \end{bmatrix}, \quad (4)$$

which implements a logical CNOT by conditionally applying $X^{\otimes \tau_B}$ on the B_{X_L} qubits. Since $X^{\otimes \tau_B}$ realizes the logical X_L operation on the encoded qubit, this construction is equivalent to a CNOT between the control qubit and the logical qubit B_L . As illustrated in Fig. 2(b), the proposed design admits $(\tau_B - 1)!$ configurations with respect to the placement of control qubits, denoted by Ct in the figure. It should be noted that symmetric configurations must be applied between the right and left sides of Fig. 2(b). In all configurations, the CNOT operations are applied exclusively to the qubits in the support of the logical operator, B_{X_L} , while the remaining qubits in the code block B_L remain unaffected. One of the fixed gates in the circuit is the CNOT operation between q and first qubit in B_{X_L} . The other two fixed CNOT gates are a result of the placement rules for controls. Let the control qubit q be assigned index 0 and indices increase going downwards along the circuit. The placement of control operations must satisfy the following constraints:

- i. The control for each CNOT gate must be placed on a qubit with a lower index than its corresponding target, excluding the qubit q (i.e., index 0).
- ii. Each qubit (except index 1) is leveraged as a target twice, and the corresponding control qubits must be placed on the same index (i.e., same qubit) to preserve the required conditional structure.

B. Optimal-depth Construction of the Proposed Design

As mentioned above, there are various configurations to realize the proposed structure by following the mentioned constraints. Circuit depth is a well-known evaluation metric, particularly in limited coherence circuits, to determine optimal construction. Therefore, in this section, we present an optimized construction that minimizes circuit depth while preserving the logical correctness of the operation. Algorithm 1 presents a systematic procedure for synthesizing the circuit with logarithmic depth, achieving $O(\log \tau_B)$ scaling with respect to the weight of the logical X_L operator on logical qubit B_L , $\tau_B = |B_{X_L}|$. This represents a significant improvement over naive constructions with linear depth. Fig. 3 illustrates an example of the resulting circuit for $|B_{X_L}| = 8$ qubits.

²The number of physical qubits on which X_L acts non-trivially.

C. Logical Qubit as Control, Single Qubit as Target

In this section, we consider the realization of a CNOT operation where a logical qubit A_L acts as the control and a single qubit q' serves as the target. Rather than implementing this operation directly, we exploit the well-known equivalence between CNOT and controlled-Z (CZ) gates via Hadamard transformations, as illustrated in Fig. 4. Specifically, the CNOT operation is equivalent to a CZ operation conjugated by Hadamard gates on the target qubit. Consequently, it suffices to construct a logical CZ operation between A_L and q' , followed by a local Hadamard on q' , as illustrated in Fig. 5.

Fig. 3: Depth Optimal CNOT for $|B_{X_L}| = 8$

Fig. 4: CNOT and CZ Equivalence

Fig. 5: CZ circuit with single qubit. (a) The desired CZ circuit between q' and A_L . (b) The proposed CZ method; it is comprised of CNOT gates and a single CZ gate. The control locations for each CNOT gate are given. However, for most of the CNOT gates, there are several possible target locations for each control. The Tg rectangles denote the possible qubit locations, with an implicit requirement for symmetry in their locations in the circuit.

Similar to the previous subsection, the key observation is that the logical action can be confined to the support of the logical CZ operator. In this case, as illustrated in Fig. 5(a), the operation only involves qubits in the support of the logical Z_L operator, denoted by $A_{Z_L} \subseteq A_L$. Since A_L is encoded using a CSS code, the logical Z_L operator can be implemented as a tensor product of Pauli- Z operators over this subset. Let $N_A = |A_L|$ and $\tau_A = |A_{Z_L}|$ denote the size of the code block B and weight of the logical Z_L operator, respectively. The desired logical CZ operation can then be expressed as the block-diagonal unitary as Equation 5.

$$U_{L-CZ} = \begin{bmatrix} I^{\otimes \tau_A} & 0^{\otimes \tau_A} \\ 0^{\otimes \tau_A} & Z^{\otimes \tau_A} \end{bmatrix}, \quad (5)$$

which implements a logical CZ by conditionally applying $Z^{\otimes \tau_A}$ on the A_{Z_L} . Therefore, any quantum circuit that realizes Equation 5 constitutes a valid implementation of the logical CZ operation.

Similar to the CNOT construction, the proposed design admits $(\tau_A - 1)!$ distinct circuit realizations due to the flexibility in assigning control-target interactions. A general representation of construction is shown in Fig. 5(b), in which the proposed design admits multiple configurations with respect to the placement of control qubits, denoted by Tg in the figure. One of the fixed gates in this circuit is the CZ gate between q' and the first qubit of A_{Z_L} , serving as the anchor of the construction. The other fixed CNOT gates are a result of the rules for placing targets of each CNOT gate. The placement of target operations must satisfy the following constraints. Let

Fig. 6: Depth Optimal CZ for $|A_{Z_L}| = 8$

the target qubit q' be assigned index 0, with indices increasing downward along the circuit.

- The target of each CNOT gate must be placed on a qubit with a lower index than its corresponding control, excluding the qubit q' (index 0).
- Each qubit (except index 1) is leveraged as a control twice, and the corresponding targets must be placed on the same index (i.e., same qubit) to preserve the required conditional structure.

Referring back to Fig. 4, we note that if we replace the only CZ gate in Fig. 5(b) with a CNOT gate with q' as the target, the modified circuit implements CNOT (where A_L is the control). This modified circuit thus has exactly $2\tau_A - 1$ local CNOT gates.

D. Optimal-depth CZ Construction

Due to the flexibility in assigning control-target pairs for the constituent CNOT gates, the proposed design admits $(\tau_A - 1)!$ distinct circuit configurations, where $\tau_A = |A_{Z_L}|$ denotes the weight of the logical Z_L operator on logical qubit A_L . To identify an optimal realization, we develop Algorithm 2, which provides a systematic procedure for constructing a circuit with minimal depth. In particular, the resulting construction achieves logarithmic depth scaling, i.e., $O(\log \tau_A)$, with respect to the size of the logical operator support. Fig. 6 illustrates an example of the optimized CZ circuit for $|A_{Z_L}| = 8$ qubits. It is worth noting that the corresponding optimal circuit for CNOT where A_L is the control would be identical except that the only CZ gate should be replaced with a CNOT gate where q' is the target.

E. CNOT Between Two Logical Qubits

We have introduced constructions for implementing CNOT operations between an arbitrary single physical qubit and an arbitrary logical qubit, covering both configurations in which the physical qubit acts as the control and as the target. Building on these primitives, we can introduce a logical CNOT operation between two encoded qubits. Let A and B in Fig. 1 be replaced by logical qubits A_L and B_L , respectively. The joint state of these logical qubits can be represented as an arbitrary two-logical-qubit state as follows:

$$|\psi_L\rangle = a|00\rangle_{A_L B_L} + b|01\rangle_{A_L B_L} + c|10\rangle_{A_L B_L} + d|11\rangle_{A_L B_L} \quad (6)$$

```

By incorporating the shared Bell pair $|\Phi^+\rangle$, the joint state of the system can be expressed as:

$$\begin{aligned}
|\psi\rangle = \frac{1}{\sqrt{2}} & (a|0\rangle_{A_L}|00\rangle_{q'q}|0\rangle_{B_L} + a|0\rangle_{A_L}|11\rangle_{q'q}|0\rangle_{B_L} \\
& + b|0\rangle_{A_L}|00\rangle_{q'q}|1\rangle_{B_L} + b|0\rangle_{A_L}|11\rangle_{q'q}|1\rangle_{B_L} \quad (7) \\
& + c|1\rangle_{A_L}|00\rangle_{q'q}|0\rangle_{B_L} + c|1\rangle_{A_L}|11\rangle_{q'q}|0\rangle_{B_L} \\
& + d|1\rangle_{A_L}|00\rangle_{q'q}|1\rangle_{B_L} + d|1\rangle_{A_L}|11\rangle_{q'q}|1\rangle_{B_L})
\end{aligned}$$

After applying the CNOT operations between A_L , B_L , and the corresponding halves of the Bell pair, the resulting state can be expressed as:

$$\begin{aligned}
|\psi\rangle = \frac{1}{\sqrt{2}} & (a|0\rangle_{A_L}|00\rangle_{q'q}|0\rangle_{B_L} + a|0\rangle_{A_L}|11\rangle_{q'q}|1\rangle_{B_L} \\
& + b|0\rangle_{A_L}|00\rangle_{q'q}|1\rangle_{B_L} + b|0\rangle_{A_L}|11\rangle_{q'q}|0\rangle_{B_L} \quad (8) \\
& + c|1\rangle_{A_L}|10\rangle_{q'q}|0\rangle_{B_L} + c|1\rangle_{A_L}|01\rangle_{q'q}|1\rangle_{B_L} \\
& + d|1\rangle_{A_L}|10\rangle_{q'q}|1\rangle_{B_L} + d|1\rangle_{A_L}|01\rangle_{q'q}|0\rangle_{B_L})
\end{aligned}$$

Applying a Hadamard gate to the second qubit of the Bell pair (qubit q) ensures the measurement is in the X -basis. The corresponding state immediately before measurement is

expressed in (9).

$$\begin{aligned}
|\psi\rangle = \frac{1}{\sqrt{2}} & (|0\rangle_{A_L}|\psi_1\rangle|0\rangle_{B_L} + |0\rangle_{A_L}|\psi_2\rangle|1\rangle_{B_L} \\
& + |1\rangle_{A_L}|\psi_3\rangle|0\rangle_{B_L} + |1\rangle_{A_L}|\psi_4\rangle|1\rangle_{B_L}) \quad (9)
\end{aligned}$$

where

$$\begin{aligned}
|\psi_1\rangle &= \frac{1}{\sqrt{2}}(a(|00\rangle_{q'q} + |01\rangle_{q'q}) + b(|10\rangle_{q'q} - |11\rangle_{q'q})) \\
|\psi_2\rangle &= \frac{1}{\sqrt{2}}(b(|00\rangle_{q'q} + |01\rangle_{q'q}) + a(|10\rangle_{q'q} - |11\rangle_{q'q})) \\
|\psi_3\rangle &= \frac{1}{\sqrt{2}}(d(|00\rangle_{q'q} - |01\rangle_{q'q}) + c(|10\rangle_{q'q} + |11\rangle_{q'q})) \\
|\psi_4\rangle &= \frac{1}{\sqrt{2}}(c(|00\rangle_{q'q} - |01\rangle_{q'q}) + d(|10\rangle_{q'q} + |11\rangle_{q'q})) \quad (10)
\end{aligned}$$

At this stage, a Z -basis measurement is applied on q' and q . The resulting measurement outcomes yield four possible combinations of classical bits, each corresponding to a distinct correction scenario. These outcomes determine the conditional logical operations that must be applied to A_L and B_L . Table II summarizes the required corrections and the corresponding resulting states. As shown, regardless of the measurement outcome, the final state is identical up to a global phase and can be expressed as follows:

$$|\psi_L\rangle = |00\rangle_{A_L B_L} + b|01\rangle_{A_L B_L} + c|11\rangle_{A_L B_L} + d|10\rangle_{A_L B_L} \quad (11)$$

IV. FAULT TOLERANCE ENHANCEMENT OF NOBOL

In this section, we propose efficient error containment approaches that complement the proposed NOBOL design. We note that physical and logical qubit errors, as well as error propagation, occur in existing approaches are not unique to NOBOL. For example, in conventional transversal implementations, a physical qubit error of A_L could propagate to B_L , potentially corrupting the encoded state. Therefore, our focus is not on eliminating errors, but on mitigating the unique aspects of error propagation induced by the NOBOL construction.

More specifically, since NOBOL applied multiple CNOT operations on A_{Z_L} and B_{X_L} , the errors are largely contained within those subsets of physical qubits. In addition, although a physical qubit error can shift its quantum state to any other quantum state, the error can always be decomposed into a linear combination of Pauli- X gates and Pauli- Z gates. Consequently, it suffices to consider to fundamental error types, i.e., bit-flip errors (X -errors) and phase-flip errors (Z -errors). We first discuss the effect of such errors on the proposed design, and then introduce two novel approaches to mitigating the effect of error propagation, including using small repetition codes tailored to NOBOL and intermittent and adaptive stabilizers (as well as their combinations) while incurring minimal additional overhead.

TABLE II: Measurement Result Corrections

Measurement Outcome	Normalized State	Correction Operation	Final State
00	$a 00\rangle_{A_L B_L} + b 01\rangle_{A_L B_L} + c 11\rangle_{A_L B_L} + d 10\rangle_{A_L B_L}$	None	$a 00\rangle_{A_L B_L} + b 01\rangle_{A_L B_L} + c 11\rangle_{A_L B_L} + d 10\rangle_{A_L B_L}$
01	$a 00\rangle_{A_L B_L} + b 01\rangle_{A_L B_L} - c 11\rangle_{A_L B_L} - d 10\rangle_{A_L B_L}$	$Z_L A_L\rangle$	$a 00\rangle_{A_L B_L} + b 01\rangle_{A_L B_L} + c 11\rangle_{A_L B_L} + d 10\rangle_{A_L B_L}$
10	$a 01\rangle_{A_L B_L} + b 00\rangle_{A_L B_L} + c 10\rangle_{A_L B_L} + d 11\rangle_{A_L B_L}$	$X_L B_L\rangle$	$a 00\rangle_{A_L B_L} + b 01\rangle_{A_L B_L} + c 11\rangle_{A_L B_L} + d 10\rangle_{A_L B_L}$
11	$-a 01\rangle_{A_L B_L} - b 00\rangle_{A_L B_L} + c 10\rangle_{A_L B_L} + d 11\rangle_{A_L B_L}$	$Z_L A_L\rangle, X_L B_L\rangle$	$-a 00\rangle_{A_L B_L} - b 01\rangle_{A_L B_L} - c 11\rangle_{A_L B_L} - d 10\rangle_{A_L B_L}$

Fig. 7: Phase-Flip Propagation in CNOT gate

A. Phase-Flip Error Propagation

In a circuit with a single CNOT gate, a Z -error occurring on the target qubit prior to the operation propagates to the control qubit, as illustrated in Fig. 7. Since quantum circuits are reversible, simultaneous Z -errors on both the control and target qubit can be simplified to an equivalent Z -error on the target qubit. This behavior plays a key role in NOBOL, in particular, for the CNOT gate between the single qubit q as the control and logical qubit B_L as the target. The symmetrical layout of CNOT gates of the NOBOL constructions ensures that a single Z -error occurring within the B_{X_L} does not propagate to other qubits in B_L , as shown in Fig. 9. However, such an error can propagate to the control qubit q , resulting in an incorrect measurement outcome. Consequently, the applied conditional correction on A_L may be incorrect, leading to a logical Z -error on A_L . This highlights a critical vulnerability of the construction and motivates the need for error containment strategies.

As for phase-flip error propagation in the CZ operation between q' and A_L , the effect of the propagation depends on the layout of the CNOT gates. Under the optimal-depth construction, if a Z -error occurs on the i -th qubit of A_{Z_L} , the number of affected qubits after propagation is given by $|A_{Z_L}|/2^{i-1}$, assuming the first qubit of A_{Z_L} is indexed as one. This relation indicates that errors originating at higher indices (i.e., lower qubit wires) propagate to fewer qubits.

B. Bit-Flip Error Propagation

The CNOT gate also propagates X -error (bit-flip error), which exhibits complementary behavior to phase-flip errors. Specifically, for a single CNOT gate, an X -error acting on the control qubit prior to the operation propagates to the target qubit, as illustrated in Fig. 8. In the NOBOL design, this

propagation behavior is similarly constrained by the circuit structure. In particular, for the CZ-based interaction between q' and A_L , the symmetric layout of the construction induces partial cancellation of propagated errors, ensuring that a single X -error remains localized and affects the qubit q' . However, such an error can still lead to an incorrect measurement outcome, which in turn results in an erroneous conditional correction and induces a logical bit-flip error on B_L . Fig. 10 illustrates this propagation behavior in the general construction.

As with phase-flip error propagation in A_{Z_L} , bit-flip error propagation within B_{X_L} is confined to the second half of the construction. Similarly, the effect of bit-flip error propagation depends on the layout of the underlying CNOT gates. Under the optimal-depth construction, if an X -error occurs on the i -th qubit of B_{X_L} , the number of affected qubits after propagation is given by $|B_{X_L}|/2^{i-1}$. This relation indicates that errors originating at higher indices propagate to fewer qubits.

C. Error Containment Techniques for NOBOL

The previous section demonstrated how error propagation can affect the correctness of the proposed operations. In this section, we introduce two complementary error containment strategies tailored to the NOBOL design. These techniques can be applied independently or jointly to effectively suppress error propagation while maintaining low overhead.

1) *Repetition Codes*: Repetition codes provide a simple yet effective mechanism for introducing redundancy by encoding a single qubit across multiple physical qubits. For instance, a bit-flip repetition code maps

$$\alpha|0\rangle + \beta|1\rangle \rightarrow \alpha|0\rangle^{\otimes n_r} + \beta|1\rangle^{\otimes n_r}, \quad (12)$$

where n_r denotes the repetition factor, while a phase repetition code similarly encodes states in the $\{|+\rangle, |-\rangle\}$ basis.

In the NOBOL design, in particular for the CNOT between A_L and B_L , the shared Bell pair can be encoded using small

Fig. 8: Bit-Flip Propagation in CNOT gate

Fig. 9: Phase Propagation with B_{X_L} . The orange Z gate represents the initial error on qubit i in the system. The blue Z gates demonstrate how the error propagates. The result is an error on qubit q and qubit i .

Fig. 10: Bit Propagation with A_{Z_L} . The orange X gate represents the initial error on qubit i in the system. The blue X gates demonstrate how the error propagates. The result is an error on qubit q' and qubit i .

repetition codes to enhance robustness. Specifically, qubit q is encoded using a bit-flip repetition code, while q' is encoded using a phase-flip repetition code to enhance their resilience to error propagation. For the CNOT operation between q and B_L , if q is encoded using a repetition code of size n_r , where $3 \leq n_r \leq |B_{X_L}|$, the B_{X_L} can be partitioned into n_r chunks (or sub-blocks). Each encoded qubit q_i then independently interacts with a corresponding subset $B_{X_{L_i}}$. The partitioning of the circuit into $n_r = 3$ sub-blocks is illustrated in Fig. 11. The proposed solution provides two key advantages.

- i. **Shallow-depth Circuits:** Independent interactions enable simultaneous execution of multiple CNOT operations, which increases parallelism, while reducing circuit depth, which eliminates decoherence concerns.
- ii. **Error Containment:** Bit-flip errors remain localized within their respective sub-blocks, increasing the tolerance of the NOBOL to bit-flip errors.

However, this approach provides asymmetric protection, in which bit-flip repetition codes protect against X -errors but not Z -errors, while phase-flip repetition codes exhibit the opposite behavior. Consequently, a trade-off arises such that increasing the repetition size n_r improves error tolerance at the cost of additional ancilla resources.

2) *Intermittent and Adaptive Stabilization:* A complementary approach to mitigating error propagation is to perform stabilization intermittently throughout the circuit execution. This strategy suppresses error accumulation by correcting errors before they propagate across multiple qubits. A key feature of NOBOL is that, although stabilizers evolve during the execution of intermediate CNOT gates, their evolution follows deterministic transformation rules. For a CNOT gate with control qubit c and target qubit t , the stabilizer transformations are given by Equation 13.

$$\begin{aligned} X_c &\rightarrow X_c X_t, & X_t &\rightarrow X_t \\ Z_c &\rightarrow Z_c, & Z_t &\rightarrow Z_c Z_t \end{aligned} \quad (13)$$

These predictable transformations enable adaptive stabilization, where stabilizers are updated dynamically to remain consistent with the evolving circuit. To illustrate the proposed stabilization strategy, consider the logical qubit B_L encoded using a 3×3 surface code, as illustrated in Fig. 12(a), which a CNOT operation is performed between q and B_L . In this case, one valid choice of the logical operator support is $B_{X_L} = \{2, 5, 8\}$. Accordingly, a valid sequence of CNOT operations is given by CNOT(5, 8), CNOT(2, 5), CNOT(q , 2), CNOT(2, 5), CNOT(5, 8). Fig. 12 illustrates the evolution of stabilizers throughout this sequence. After CNOT(5, 8), the stabilizers are updated as Equation 14.

$$\begin{aligned} X_2 X_3 X_5 X_6 &\rightarrow X_2 X_3 X_5 X_6 X_8 \\ X_4 X_5 X_7 X_8 &\rightarrow X_4 X_5 X_7 \\ Z_5 Z_6 Z_8 Z_9 &\rightarrow Z_6 Z_8 Z_9 \end{aligned} \quad (14)$$

This transformation corresponds to Fig. 12(b). As shown in Fig. 12(c), after CNOT(2, 5), the stabilizers evolve as Equation 15.

$$\begin{aligned} X_1 X_2 &\rightarrow X_1 X_2 X_5 \\ X_2 X_3 X_5 X_6 X_8 &\rightarrow X_2 X_3 X_6 X_8 \\ Z_1 Z_2 Z_4 Z_5 &\rightarrow Z_1 Z_4 Z_5 \end{aligned} \quad (15)$$

The operation CNOT(q , 2) does not modify the stabilizers of B_L , as it does not involve an internal CNOT gate. The subsequent operations reverse the earlier transformations, such that after the second CNOT(2, 5), the stabilizers revert to those in Fig. 12(b), and after the final CNOT(5, 8), the stabilizers return to their original configuration in Fig. 12(a).

This example demonstrates that stabilizers can be updated consistently throughout the circuit, enabling intermediate error correction without disrupting the logical state. However, the frequency of stabilization introduces a trade-off between error suppression and execution time. While performing stabilization after each CNOT gate minimizes error propagation, it increases circuit depth. In general, each stabilization round incurs $O(d)$ depth, where d is the code distance. Since the circuit consists of $2\tau_B$ CNOT operations, where $\tau_B = |B_{X_L}|$, the worst-case depth scales as $2\tau_B * O(d) = O(\tau_B d)$. A similar analysis applies to the CNOT operation between q' and A_L .

Fig. 11: q_1 , q_2 , and q_3 form a three qubit bit repetition code. Each qubit q_i independently performs a CNOT operation with each chunk $B_{X_{Li}}$ which, all together, forms a CNOT operation between a three qubit repetition code and B_L .

Fig. 12: Evolution of surface code stabilizers during the CNOT circuit. Blue qubits represent data qubits, green qubits correspond to Z stabilizers, and orange qubits denote X stabilizers. Arrows indicate the direction of CNOT gates used for stabilization.

3) *Combined Error Containment Strategy*: The above techniques can be combined to further enhance fault tolerance. Specifically, repetition codes localize errors, while intermittent stabilization removes accumulated errors across the entire code. This combined strategy enables simultaneous containment of both bit-flip and phase-flip errors.

While the combined approach improves robustness, it introduces a trade-off between resource overhead and execution latency. Larger repetition codes require additional ancilla qubits, while more frequent stabilization increases circuit depth. Nevertheless, these trade-offs can be tuned based on hardware constraints and target logical error rates, making the approach highly adaptable to practical quantum computing systems.

V. CONCLUSION

In this paper, we have introduced NOBOL, a novel low-overhead approach for realizing *long-distance or non-neighboring, logical gate* operations using only a single entangled state, along with local operations and classical computing. It enables efficient implementation of logical CNOT operations across both monolithic and distributed quantum architectures.

We have also illustrated the structural flexibility of the proposed design, which admits a factorial number of circuit configurations due to the freedom in qubit ordering that makes

it well-suited across various qubit modalities and connectivity constraints. We have demonstrated that NOBOL admits a depth-optimal construction with logarithmic depth scaling, making it well-aligned with coherence-time limitations in fault-tolerant quantum systems. Moreover, the code-agnostic nature of the NOBOL allows it to be applied to a broad class of CSS codes, including the well-known surface codes. Furthermore, we developed unique containment techniques for error propagation, including intermittent and adaptive stabilization and encoding each half of the entangled pair using small repetition codes, which provide a flexible trade-off between ancilla qubits and execution time.

In summary, NOBOL offers a practical and scalable solution for large-scale fault-tolerant quantum computing, particularly in architectures with limited inter- and intra-QPU connectivity and constrained ancilla resources. It also greatly benefits logical gate operation across a Quantum Internet where networking resources are even more scarce and end-to-end entangled connections are even more fragile. While this work has laid down the solid theoretical and algorithmic foundations, there remains much further work, including quantitative evaluation of fault-tolerance performance, and the design and analysis of optimal error-containment strategies.
